Credits

DGGRID was primarily written in C++ by Kevin Sahr. See the file **CHANGELOG.md** that comes with the source code for additional contributors.

The original **DGGRID** specifications were developed by (in alphabetical order): A. Ross Kiester, Tony Olsen, Barbara Rosenbaum, Kevin Sahr, Ann Whelan, and Denis White.

DGGRID was made possible in part by funding from the US Environmental Protection Agency, PlanetRisk, Inc., Culmen International, the Ruhr-University Bochum/GeoInsight Project, Turtle Conservancy, and the University of Tartu Landscape Geoinformatics Lab.

DGGRID can optionally make use of the following external library (not included):

• The Open Source Geospatial Foundation's GDAL translator library for raster and vector geospatial data formats (see <u>gdal.org</u>)

DGGRID uses the following third-party libraries (included with the **DGGRID** source code):

- Angus Johnson's Clipper library; see http://www.angusj.com.
- George Marsaglia's multiply-with-carry "Mother-of-all-RNGs" pseudo-random number generation function.
- The gnomonic projection code is adapted from Gerald Evenden's PROJ.4 library
- Frank Warmerdam's Shapelib library

The github source code distribution contains instructions on building **DGGRID**. The examples directory contains example **DGGRID** metafiles (with associated input files).

DGGRID version 8.41 was released May 31, 2025 www.discreteglobalgrids.org https://github.com/sahrk/DGGRID

1. Introduction

DGGRID is a command-line application designed to generate and manipulate icosahedral discrete global grids (DGGs) [Sahr et al., 2003]. A single execution of **DGGRID** can perform one of six distinct operations:

- **1.** *Grid Generation from clipping polygons*. Generate the cells of a DGG, either covering the complete surface of the earth or covering only a specific set of regions on the earth's surface.
- **2.** *Grid Generation from points.* Generate the cells of a DGG, either covering the complete surface of the earth or covering only a specific set of regions on the earth's surface.
- **3.** *Point Value Binning*. Bin a set of floating-point values associated with point locations into the cells of a DGG, by assigning to each DGG cell the arithmetic mean of the values which are contained in that cell.
- **4.** *Presence/Absence Binning*. Given a set of input files, each containing point locations associated with a particular class, **DGGRID** outputs, for each cell of a DGG, a vector indicating whether or not each class is present in that cell.
- **5.** *Address Conversion*. Transform a file of locations from one address form (such as longitude/latitude) to another (such as DGG cell indexes).
 - **6.** Output Grid Statistics. Output a table of grid characteristics for the specified DGG.

DGGRID is designed to be run from the Unix command line. **DGGRID** requires a single command line argument, the name of a "metafile," which is a plain text file that describes the actions that **DGGRID** is to perform in that run. Thus **DGGRID** is executed by typing at the command line:

dggrid metaFileName.meta

The metafile consists of a series of key-value pairs that tell **DGGRID** how to proceed. The format of this metafile is described in the next section. The rest of the sections in this documentation give more detail on setting up metafile parameters to control the execution of **DGGRID**.

page 2 of 59

2. Metafile Format

Metafiles are text files in which each line is either a comment, a blank line, or a key-value pair that designates the value of a parameter for **DGGRID**. Blank lines are ignored by **DGGRID**. Lines beginning with '#' are comments and are also ignored by **DGGRID**.

A parameter is specified by a single line of the form:

parameterName value

Parameter names are not case sensitive. A parameter can be of one of five types. The five parameter types, with a description of their legal values, are:

- 1. boolean. Legal values are TRUE and FALSE (case sensitive).
- 2. **integer**. Any integer is a legal value.
- 3. **double**. Any real number, specified in decimal form, is a legal value.
- 4. **string**. The remainder of the line following the parameter name is interpreted as the value.
- 5. **choice**. Legal values consist of one of a finite set of keywords specific to that parameter. The values of choice parameters are not case sensitive but by convention are usually written in all capital letters.

Some parameters are only used for specific operations or when specific other parameter conditions prevail. All parameters have a default value which is used if no value is specified. Detailed information on each parameter is given in the following sections and in **Appendix A**. Repeating a parameter specification within the same metafile over-writes the previously specified value; the last value given for a particular parameter will be used.

Note that a number of parameters from previous versions of **DGGRID** are still active in the code but are not described in this documentation; that is because those parameters have not been fully integrated with the new features in this beta release. Those parameters will be fully restored in a future release.

See the examples directory in the **DGGRID** source code distribution for examples of **DGGRID** metafiles.

3. General Parameters

In this section we describe the parameters which are used by every run of **DGGRID**.

As described in **Section 1**, each run of **DGGRID** consists of one of five distinct modes of operation. The operation is specified using the **choice** parameter dggrid_operation. The allowable values for this parameter are:

```
GENERATE_GRID - perform grid generation from polygons (see Sections 6)

GENERATE_GRID_FROM_POINTS - perform grid generation from points (see Section 8)

BIN_POINT_VALS - perform point value binning (see Section 9)

BIN_POINT_PRESENCE - perform presence/absence binning (see Section 10)

TRANSFORM_POINTS - perform address conversion (see Section 11)

OUTPUT STATS - output a table of grid characteristics (see Section 12)
```

All operation modes require the specification of a single DGG. The parameters for specifying a DGG are described in **Section 4**.

The **integer** parameter precision specifies the number of digits to the right of the decimal place **DGGRID** is to use when outputting floating point numbers, including latitude/longitude values.

The parameters verbosity, pause_on_startup, and pause_before_exit exist solely to support debugging and can be ignored by users. These parameters are described below.

The **integer** parameter **verbosity** is used to control the amount of debugging information which is printed by **DGGRID**. Valid values are from 0 to 3. The default value, 0, gives minimal output, which includes the value of all active parameter settings. It is not recommended that you increase this value.

Setting either of the **boolean** parameters <code>pause_on_startup</code> and/or <code>pause_before_exit</code> to TRUE causes **DGGRID** to pause execution either immediately after loading parameters, or just before program termination, respectively. The default value for both parameters is FALSE.

4. Specifying the DGG

Background

As described in [Sahr et al., 2003], a DGG system can be specified by a set of independent design choices. The first design choice is the desired base polyhedron; **DGGRID** can generate DGGs that have an icosahedron as their base polyhedron. The remaining primary design choices are:

- **1.** The orientation of the base polyhedron relative to the earth.
- **2.** The hierarchical spatial partitioning method defined symmetrically on a face (or set of faces) of the base polyhedron. This usually includes specifying the cell topology and an *aperture*, which determines the area ratio between cells at sequential resolutions.
- 3. The transformation between each face and the corresponding spherical surface.
- **4.** The resolution (or degree of recursive partitioning).

The current version of **DGGRID** supports DGGs that use either the Icosahedral Snyder Equal Area (ISEA) projection [Snyder, 1992] or the icosahedral projection of R. Buckminster Fuller [1975] (as developed analytically by Robert Gray [1995] and John Crider [2008]). **DGGRID** can generate grids with cells that are triangles, diamonds, or hexagons. Grids with a triangle or diamond topology must use an aperture of 4, while hexagon grids can use an aperture of 3, 4, 7, or an arbitrary mixed sequence of those apertures. **DGGRID** also supports specifically designed "preset" DGGs, including the mixed aperture hexagonal grids the US EPA **Superfund_500m** DGG (see **Appendix E**), and the PlanetRisk DGG (see **Appendix F**).

Detailed information about the parameters that specify each of the DGG design choices are given below, along with a discussion on specifying the spherical earth radius.

Preset DGG Types

DGGRID provides a number of preset DGG types for your use. A preset type can be chosen by specifying one of the following values for the **choice** parameter dggs_type:

CUSTOM (default) - indicates that the grid parameters will be specified manually (see below)

SUPERFUND - the **Superfund_500m** grid (see **Appendix E**)

PLANETRISK - the PlanetRisk grid (see Appendix F)

ISEA4T - ISEA projection with triangle cells and an aperture of 4

ISEA4D - ISEA projection with diamond cells and an aperture of 4

ISEA3H - ISEA projection with hexagon cells and an aperture of 3

ISEA4H - ISEA projection with hexagon cells and an aperture of 4

ISEA7H - ISEA projection with hexagon cells and an aperture of 7

ISEA43H - ISEA projection with hexagon cells and a mixed sequence of aperture 4 resolutions followed by aperture 3 resolutions

FULLER4T - FULLER projection with triangle cells and an aperture of 4

```
FULLER4D - FULLER projection with diamond cells and an aperture of 4

FULLER3H - FULLER projection with hexagon cells and an aperture of 3

FULLER4H - FULLER projection with hexagon cells and an aperture of 4

FULLER7H - FULLER projection with hexagon cells and an aperture of 7

FULLER43H - FULLER projection with hexagon cells and a mixed sequence of aperture 4 resolutions followed by aperture 3 resolutions
```

Each preset grid type sets appropriate values for all of the parameters that specify a DGG. The default values for each preset grid type are given in **Appendix B**. These default preset values can be overridden by explicitly setting the desired individual parameters in your metafile as described below. In particular, note that all preset grid types have a default resolution; your desired DGG resolution should be specified using the parameter dggs res spec (see below).

Appendix D gives some statistics on the individual resolutions of the hexagonal ISEA preset DGGs.

Manually Setting DGG Parameters

The following parameters are used to describe a specific DGG instance.

1. Specifying the orientation: The orientation of a DGG base icosahedron relative to the earth can be specified explicitly, randomly determined, or set so that a specified point is maximally distant from icosahedron vertices, by setting the **choice** parameter dggs_orient_specify_type to SPECIFIED, RANDOM, or REGION_CENTER respectively.

If dggs_orient_specify_type is set to SPECIFIED the DGG orientation is determined by the location of a single icosahedron vertex and the azimuth from that vertex to an adjacent vertex. The **double** parameters dggs_vert0_lon and dggs_vert0_lat are used to specify the location of the vertex, and the **double** parameter dggs_vert0_azimuth to specify the azimuth to an adjacent vertex; all or these parameters are in decimal degrees. Note that the default DGG placement, which is symmetrical about the equator and has only a single icosahedron vertex falling on land, is specified by:

```
dggs_vert0_lon 11.25
dggs_vert0_lat 58.28252559
dggs_vert0_azimuth 0.0
```

If dggs_orient_specify_type is set to RANDOM the orientation of the DGG is randomly determined. All parameter values (including the randomly generated values for a vertex location and azimuth used to orient the grid) will be output for your information to the file specified by the string parameter dggs_orient_output_file_name. Some control over the random specification of the grid orientation is afforded by the choice parameter rng_type and the integer parameter dggs_orient_rand_seed. The choice parameter rng_type indicates which pseudo-random number generator to use. A value of RAND indicates that the C standard

library rand/srand functions should be used. A value of MOTHER (the default) indicates that George Marsaglia's "Mother-of-all-RNGs" function should be used. The seed value for **DGGRID** to use to initialize the pseudo-random number sequence can be set using the **integer** parameter dggs_orient_rand_seed.

If the current operation involves only a small region on the earth's surface it is often convenient to orient the grid so that no icosahedron vertices occur in the region of interest. Such an orientation can be specified by setting dggs_orient_specify_type to REGION_CENTER and then specifying the center point of the region using the **double** parameters region_center_lon and region_center_lat (both in decimal degrees).

All operations require that at least one DGG be specified. A single DGG may be used by setting the **integer** parameter dggs_num_placements to 1 (the default). Alternatively, you may perform the desired operation on multiple DGGs by setting dggs_num_placements to the desired number. If the grid orientation is randomly chosen, this will perform the desired operation on multiple randomly oriented grids. The parameters for each grid will be output to a separate file based on the value of dggs_orient_output_file_name, with an additional suffix indicating the grid number (0001 to 000n where n equals the value of dggs_num_placements). This suffix will also be used to designate the corresponding output files (as specified in the particular operation being performed). Note that if dggs_orient_specify_type is set to any value other than RANDOM all of the grids generated will have exactly the same orientation.

2. Specifying the hierarchical spatial partitioning method: The hierarchical partitioning method used to generate the DGG is specified by choosing a grid topology and aperture (defined as the ratio of areas between cells in a given DGG resolution and the next finer resolution). The topology is specified using the **choice** parameter dggs_topology with one of the values: HEXAGON (default), TRIANGLE, or DIAMOND.

DGGRID can create grids that are produced using a single aperture, as well as hexagon grids produced using a mixed aperture of some number of aperture 4 resolutions followed by aperture 3 resolutions, or hexagon grids with an arbitrary mixed aperture sequence of resolutions. The type of aperture sequence is specified using the **choice** parameter dggs_aperture_type with a value, respectively, of either PURE (default), MIXED43, or SEQUENCE.

If a PURE aperture type is specified then the desired aperture is specified with the **integer** parameter dggs_aperture. The valid values for aperture are dependent on the chosen topology. **DGGRID** can create HEXAGON DGGs with an aperture of 3, 4, or 7, and DIAMOND and TRIANGLE DGGs with an aperture of 4.

If a MIXED43 aperture type is specified then the parameter dggs_aperture is ignored. Instead, the **integer** parameter dggs_num_aperture_4_res (default 0) specifies the number of resolutions which use aperture 4; the remaining grid resolutions up to the desired grid resolution (see the next subsection) are generated using aperture 3. Note that the parameter

dggs_num_aperture_4_res is ignored unless dggs_aperture_type is MIXED43. Only HEXAGON topology grids may use the MIXED43 aperture type.

If a SEQUENCE aperture type is specified then the parameter dggs_aperture is ignored. Instead, the aperture sequence for the DGGS must be specified as a string of 3's, 4's, and/or 7's in the **string** parameter dggs aperture sequence (default "333333333333").

- **3. Specifying the projection:** The regular polygon boundaries and points associated with DGG cells are initially created on the planar faces of an icosahedron; they must then be inversely projected to the sphere. The desired projection to use for this is specified by the **choice** parameter dggs_proj. The valid values are ISEA, which specifies the Icosahedral Snyder Equal Area projection [Snyder, 1992], or FULLER, which specifies the icosahedral Dymaxion projection of R. Buckminster Fuller [1975] (as developed analytically by Robert Gray [1995] and John Crider [2008]). The ISEA projection creates equal area cells on the sphere at the expense of relatively high shape distortion, while the Fuller projection strikes a balance between area and shape distortion. See Gregory et al. [2008] for a more detailed discussion of these trade-offs.
- **4. Specifying the resolution:** The desired DGG resolution can be specified using one of three methods chosen using the **choice** parameter dggs_res_specify_type with one of the following values:
 - SPECIFIED (default) the desired resolution is explicitly specified by setting the value of the integer parameter dggs_res_spec (default 9).
 - CELL_AREA the desired resolution is set to the DGG resolution whose average cell area is closest to the area specified by the **double** parameter dggs_res_specify_area (in square kilometers).
 - INTERCELL_DISTANCE the desired resolution is set to the DGG resolution whose approximate intercell distance is closest to the distance specified by the **double** parameter dggs_res_specify_intercell_distance (in kilometers). Note that the intercell distance calculation is performed on the plane, and therefore is only useful as a relative measure. See **Appendix D** for empirically derived intercell statistics for some of the hexagonal ISEA preset grid types.

If CELL_AREA or INTERCELL_DISTANCE is specified, then the desired area or intercell distance (as applicable) is rounded up or down to the nearest grid resolution based on the value of the **boolean** parameter dggs_res_specify_rnd_down; a value of TRUE indicates round down, a value of FALSE indicates round up. The chosen resolution is always output by **DGGRID** for your information. The calculation of cell areas and intercell distances uses the value specified for the earth radius (see **Subsection 5** below).

In general, **DGGRID** will attempt to generate grids up to a maximum resolution of **35**. For grids with a dggs_aperture_type of SEQUENCE, the maximum resolution **DGGRID** will attempt is determined by the length of the value of the string parameter

dggs_aperture_sequence. If the dggs_type is specified to be SUPERFUND then the only supported value for dggs_res_specify_type is SPECIFIED, and the maximum resolution is 9.

However, the maximum resolution which can actually be successfully generated by **DGGRID** is a function of the specified grid topology, projection, the size of data types on the machine on which **DGGRID** is compiled and executed, and the location of the generated grid region relative to the faces of the underlying icosahedron. When generating very high resolution grids the user should be aware that, even if **DGGRID** reports success, the indexes and output cell geometries should be validated to make sure that they are not degenerate.

5. Specifying the earth radius: The **choice** parameter proj_datum specifies a datum that **DGGRID** will use to determine the spherical radius of the earth. The legal values for this parameter are given below, along with the earth radius that they indicate:

```
WGS84_AUTHALIC_SPHERE (default): 6371.007180918475 km
WGS84_MEAN_SPHERE: 6371.0087714 km
```

CUSTOM_SPHERE: the earth radius (in kilometers) will be read from the **double** parameter proj_datum_radius

Note that the earth radius is *not* used in the process of generating grid geometries in geodetic coordinates; such generation is performed on a unit sphere. The radius is only used in determining the grid resolution (when dggs_res_specify_type is not SPECIFIED) and in generating grid statistics in kilometers.

5. Specifying Per-Cell Grid Output

Any run of **DGGRID** which produces a set of grid cells (**choice** parameter dggrid_operation values GENERATE_GRID, GENERATE_GRID_FROM_POINTS, TRANSFORM_POINTS, BIN_POINT_VALS, or BIN_POINT_PRESENCE) can generate, for the specified cells, any of the following: cell boundaries, center points, topological neighbors, and/or spatial hierarchy children. Each type of data can be output to a separate file, each with its own file format, or some or all of the data for each cell can be combined in a single output file.

All DGG cell boundaries and center points output from **DGGRID** are given in geodetic (longitude/latitude) coordinates in decimal degrees.

The **choice** parameters **cell_output_type** and **point_output_type** specify the desired output file format for cell boundaries and cell points respectively. Each of these parameters may have the following values:

NONE - indicates that no output of that type will be performed

AIGEN - indicates that the cell/point output should be in ARC/INFO Generate file format (see Section 5).

SHAPEFILE - indicates that the cell/point output should be in ESRI Shapefile format

KML - indicates that the cell/point output should be in KML (Google Earth) format

GEOJSON - indicates that the cell/point output should be in GeoJSON format

GDAL - indicates that the cell/point output should be a GDAL-compatible file format

GDAL_COLLECTION - indicates that the cell/point geometry output should be combined with other cell information in a GDAL-compatible file format

TEXT - indicates that text file output in an operation-specific format (point output type only)

Note that **DGGRID** must be built with GDAL in order to use the output types GDAL or GDAL_COLLECTION.

A value of GDAL for parameter cell_output_type and/or point_output_type requires that the type of GDAL-compatible vector file format (see gdal.org) be specified as the value of the string parameter cell_output_gdal_format and/or point_output_gdal_format respectively. Note that under the current implementation the

GDAL SHAPEFILE format has trouble handling file names that contain directory path information. In such a situation we suggest that you use the SHAPEFILE output type instead (which does not make use of GDAL).

The file name prefix to use for the boundary or point output file is specified using the **string** parameter cell_output_file_name or point_output_file_name respectively. **DGGRID** will add the appropriate file suffix to the specified prefix name, depending on the chosen file format.

DGG output files created by **DGGRID** can be quite large, depending on the size of the region being generated and the resolution of the grid. The generated cell boundaries and/or points can be output across multiple files by setting the **integer** parameter max_cells_per_output_file to the maximum number of cells to output to a single file. Setting the parameter to 0 (the default) will cause **DGGRID** to output all cells to a single file, no matter how large. If max_cells_per_output_file is greater than 0, output files are distinguished by appending a "_1", "_2", etc. to each output file name.

Since cell boundaries are only true regular polygons in the chosen projection space it may be desirable to introduce additional points into the cell edges to better preserve the boundary shape after inverse projection to longitude/latitude coordinates. The number of additional points to introduce into each edge is specified by the **integer** parameter densification. A value of 0 (the default) indicates that no densification should be performed.

By default, each longitude value is output in the range -180.0 to 180.0 degrees. When visualized using a 2D program, cells that straddle the anti-meridian can appear to "wrap" across the image. The choice parameter longitude_wrap_mode can be used to force the output vertex longitudes of such cells to be entirely positive (value UNWRAP_EAST), entirely negative (value UNWRAP_WEST), or to follow the default behavior (the default value WRAP). Setting the boolean parameter unwrap_points to TRUE (the default value) forces each output cell center point to follow the associated cell when it is unwrapped, so that cells and points will display together in a 2D program. Note that some GDAL-output file formats (e.g., GDAL KML) clamp the longitude range to -180.0 to 180.0 degrees; in those cases unwrapping will be effectively (and silently) ignored.

A unique integer cell identifier is output along with each cell boundary or point. The integer identifier type is specified using the **choice** parameter output_cell_label_type, which can have one of four values:

GLOBAL_SEQUENCE (default when dggs_type is not SUPERFUND) - the identifier is the appropriate value in a linear sequence 1 to *n*, where *n* is the total number of cells in the whole earth DGG

- ENUMERATION the generated cells are numbered from 1 to n, where n is the total number of cells generated
- OUTPUT_ADDRESS_TYPE the identifier is output in the form indicated by the **choice** parameter output_address_type (see **Appendix** C).
- SUPERFUND (preset default when dggs_type is SUPERFUND) the identifier is a condensed Superfund_500m index (see **Appendix D**). This value must be (and can only be) used when dggs_type is SUPERFUND.

Note that DGGRID provides two ways to generate output in either ESRI Shapefile format or KML:

- 1. Set cell_output_type and/or point_output_type to SHAPEFILE or KML, or
- 2. Set cell_output_type and/or point_output_type to GDAL and cell_output_gdal_format and/or point_output_gdal_format to SHAPEFILE or KML

When output is to an ESRI Shapefile the cell identifier is stored in a global_id field. The ESRI Shapefile format limits integer fields to 32-bit integer size, which is not sufficient for storing the identifiers associated with high resolution DGGs. Therefore **DGGRID** creates the Shapefile field **global_id** as a fixed width string with a width specified by the **integer** parameter shapefile id field length (default 11).

The color and width of KML output cell boundaries can be controlled using the **string** parameter kml_default_color (default fffffff or opaque white) and the **integer** parameter kml_default_width (default 4) respectively. KML color values are expressed in 8 digit hexadecimal notation of the form *aabbggrr*, with two hexadecimal digits (00 to ff) each for the alpha, blue, green, and red components.

In addition to outputting the boundaries and center points of the selected cells, **DGGRID** can output the topological neighbors of each of the cells; i.e., the DGG cells that are adjacent to/share an edge with each cell. **DGGRID** currently only supports neighbors for hexagon and diamond grids (not triangle grids). To output cell neighbors, set the **choice** parameter neighbor_output_type to TEXT. Specify the name of the output neighbors file in the **string** parameter neighbor_output_file_name. For each selected cellID the output file will contain a single line of the form:

cellID neighborID₁ neighborID₂ ... neighborID_n

with the neighborID's for each cell listed in counter-clockwise order about the central cellID cell.

DGGRID can also output the spatial children of the selected cells. That is, for each of the selected cells, **DGGRID** will determine and output the cells in the next finer resolution of the DGGS which intersect or are contained within the selected cell. To output cell spatial children, set the **choice** parameter **children_output_type** to **TEXT**. Specify the name of the output children file in the **string** parameter **children_output_file_name**. For each selected **cellID** the output file will contain a single line of the form:

cellID childID1 childID2 ... childIDn

So far we have discussed outputting each type of cell data to a different output file. One or more of the features associated with each cell may be output together in a single file by specifying the output type GDAL_COLLECTION for each such desired feature (cell_output_type, point_output_type, neighbor_output_type, and/or children_output_type). The chosen features must include either the cell boundary, point, or both. The output file format for this single collection file is specified in the string parameter collection_output_gdal_format, as described above for the parameters cell_output_gdal_format and point_output_gdal_format. Note that some GDAL formats may not support the output of neighbors or children. The file name prefix to use for this collection file is specified using the string parameter collection output file name.

6. Grid Generation: Whole Earth or Clipping Polygons

Specifying the value GENERATE_GRID for the **choice** parameter dggrid_operation will tell **DGGRID** to create all, or some portion of, the specified DGG (see the previous section). The **choice** parameter clip_subset_type controls the amount of the grid that will be generated. Setting the parameter clip_subset_type to WHOLE_EARTH will generate the entire earth at the specified resolution.

A subset of WHOLE_EARTH sequential cell IDs can be generated by specifying the first and last sequence numbers to generate by setting the values of the **integer** parameters output first seqnum and output last seqnum respectively.

DGGRID provides three methods for generating a subset of the specified DGG. The portion of the grid to be generated can be specified by:

- one or more files containing clipping polygons that indicate the regions to be generated (clip subset type values AIGEN, SHAPEFILE, or GDAL)
- one or more text files containing the cell sequence numbers of the grid cells to be generated (clip_subset_type value SEQNUMS)
- the cell sequence numbers of one or more coarser resolution cells to use as clipping
 polygons to indicate the regions to be generated (clip_subset_type values
 COARSE_CELLS)

Each of these methods is discussed below. Note that **DGGRID** must be built with GDAL to make use of GDAL file formats.

A DGG that covers a portion of the earth's surface can be generated by specifying one or more files containing the clipping polygons which **DGGRID** will use to determine the portion of the grid to generate. **DGGRID** supports three types of clipping files: ARC/INFO Generate files, ESRI Shapefiles, and vector file formats readable by GDAL. To specify a clipping file format, set the parameter clip subset type to AIGEN, SHAPEFILE, or GDAL respectively.

If clip_subset_type is set to AIGEN, SHAPEFILE, or GDAL then the string parameter clip_region_files should be set to a space-delimited list of file names, in the specified format, containing polygons to use for clipping. If clip_subset_type is GDAL then the files must be in a GDAL-readable vector format (see gdal.org). The polygons must be specified using geodetic (latitude/longitude) coordinates. Limitations in **DGGRID** require that each clipping polygon be no more than approximately 60° of great circle arc in extant in any direction. The exact limitation is determined by the relationship between each polygon and the underlying icosahedron; **DGGRID** will let you know if a polygon is too large for the grid generation you are attempting. In that event you must break the polygon into smaller polygons before using it in a clipping file.

When clip_subset_type is set to GDAL **DGGRID** will correctly handle holes in the clipping polygons if the **boolean** parameter clip_using_holes is set to TRUE (the default value is FALSE). Cells that intersect a polygon but are entirely contained in one of that polygon's holes will not be chosen. Note that **DGGRID** will interpret holes as regular polygons in non-GDAL input files.

The polygon intersection library uses an integer grid, the coarseness of this grid is determined by the parameter clipper_scale_factor. Clipping with a low resolution grid can sometimes produce incorrect results; if this occurs try increasing the value of clipper_scale_factor (the default value is 1000000). But note that doing so may limit the extent of the region that can be clipped.

Intersections between the clipping polygons and the DGG cells are performed in the specified DGG projection space, with the great circle arcs between adjacent vertices in the original clipping polygons transformed into straight lines on the projection plane. If adjacent vertices in the original clipping polygons are too far apart this may result in an inaccurate representation of the region boundary in the clipping space. This effect can be minimized by introducing additional points into the great circle arcs before projection. Setting the double parameter <code>geodetic_densify</code> to some arc length (in decimal degrees) will cause <code>DGGRID</code> to introduce extra points into each edge arc so that no two vertices are more than the specified distance apart. Setting <code>geodetic_densify</code> to <code>0.0</code> (the default) indicates that no such densification is to be performed.

Alternately, in hexagon (only) grids the clipping regions to be generated can be the cell boundaries of one or more cells in some coarser resolution of the current multi-resolution DGGS (see Section 4). This is indicated by setting the parameter clip subset type to COARSE CELLS. The integer parameter clip cell res must be set to the desired coarser resolution. The resolution must be less than the resolution of the cells being generated (as specified in **Section 4**), and must be greater than zero (because resolution 0 cells do not meet the clipping polygon intersection algorithm requirements, as described above). One or more cell sequence numbers from this coarser resolution grid must be specified, space delimited, in the parameter clip cell segnums. The boundaries of these cells are then used as the input clipping polygons, as described above, including possible edge densification based on the value of parameter geodetic densify. Because that approach to densification can result in an unnecessary number of vertexes and impact performance, we recommend instead using the integer parameter clip_cell_densification, which specifies a number of additional points to introduce into each cell edge prior to projection. We recommend using a value of 1 (the default) for very coarse resolutions to avoid anomalous results. A value of 0 indicates that no densification of these coarse clipping cells should be performed.

The cells for a given set of cell sequence numbers can be generated by setting the parameter clip subset type to SEQNUMS (this is not supported for grids with a

dggs_aperture_type of SEQUENCE). Then clip_region_files must be set to one or more text files containing the list of cell sequence numbers to be generated. A single cell will be generated at most once; duplicate sequence numbers in the input will be ignored.

Note that a single execution of **DGGRID** can take several hours (or more!), depending on the resolution of the grid being generated and the number and complexity of the clipping polygons (we recommend reducing the number of vertices in clipping polygons whenever possible). You can control the frequency of feedback during grid generation by setting the integer parameter update_frequency. The value of this parameter specifies the number of cells that will be tested for inclusion before outputting a status update. The default value is 100000.

The per-cell output for the generated cells can be specified as described in Section 5. In addition, the parameter point_output_type has an additional value TEXT which will output the cell points, one-per-line, formatted as:

cellID, longitude, latitude

page 16 of 59

7. Specifying Point File Input

The **choice** parameter dggrid_operation values GENERATE_GRID_FROM_POINTS, BIN_POINT_VALS, TRANSFORM_POINTS, and BIN_POINT_PRESENCE specify operations that take input from files containing point locations. The input file format is specified by the **choice** parameter point_input_file_type, which can have a value of TEXT or GDAL (assuming **DGGRID** was built with the GDAL library).

The specific format for TEXT file input for each operation is described in the **Section** for that operation. The values in a TEXT file must be delimited by the character indicated within double quotes in the string parameter input delimiter.

The operation TRANSFORM_POINTS currently only takes TEXT input; GDAL input files can not be used with that operation.

A single input file can be specified using the **string** parameter input_file_name. Multiple input files can be specified by setting the **string** parameter input_files to a space-delimited list of file names, in the specified format, containing points to use as input. If point_input_file_type is GDAL then the input file(s) must be in a GDAL-readable vector format (see <u>gdal.org</u>). The points must be specified using geodetic (latitude/longitude) coordinates.

If the input locations cover a substantial portion of the earth's surface, then the choice parameter bin_coverage should be set to GLOBAL. If the locations covers only a relatively small portion of the earth's surface then bin_coverage should be set to PARTIAL. This allows **DGGRID** to make trade-offs between speed and memory usage. GLOBAL location sets are processed more quickly, but may fail at higher DGG resolutions due to memory restrictions. PARTIAL location sets are processed more slowly, but can enable the use of higher resolution DGGs (depending on the actual extent of the input locations).

page 17 of 59

8. Grid Generation: Point Binning

Specifying the value GENERATE_GRID_FROM_POINTS for the **choice** parameter dggrid_operation will tell **DGGRID** to generate the cells of the specified DGG (see **Section 4**) that contain one or more of the points contained in the input files (specified as described in **Section 7**).

If the **boolean** parameter output_count is set to TRUE (the default is FALSE), for each output cell the number of input points that are contained in that cell is output in the cell field with the field name specified in the **string** parameter output_count_field_name (default value "count").

page 18 of 59

9. Binning Point Values

Setting the choice parameter dggrid_operation to BIN_POINT_VALS tells **DGGRID** to bin a set of floating-point data values associated with geodetic coordinates into the cells of a DGG(s) specified as per **Section 4**. The binning is performed by assigning to each DGG cell the arithmetic mean of the values associated with the input points that are contained in that cell. The input file(s) containing the points to be binned are specified as described in **Section 7**.

If the input files are in GDAL format (**choice** parameter point_input_file_type has value GDAL), then the value for each input point is taken from the field named as specified in the **string** parameter input_value_field_name (default "value").

If the input files are in TEXT format (**choice** parameter point_input_file_type has value TEXT), then each line in each input file should consist of a longitude, a latitude (both in decimal degrees), and a single floating-point value. These three values must be delimited by the character indicated within double quotes in the string parameter input_delimiter.

If the **boolean** parameter output_mean is set to TRUE (the default), for each output cell the arithmetic mean of the values associated with all input points that are contained in that cell is output in the cell field with the field name specified in the **string** parameter output mean field name (default value "mean").

If the **boolean** parameter output_count is set to TRUE (the default is FALSE), for each output cell the number of input points that are contained in that cell is output in a cell field with the field name specified in the **string** parameter output_count_field_name (default value "count").

If the **boolean** parameter output_total is set to TRUE (the default is FALSE), for each output cell the total summation of the values associated with all input points that are contained in that cell is output in a cell field with the field name specified in the **string** parameter output_total_field_name (default value "total").

In addition to the standard per-cell output described in **Section 5**, **DGGRID** can output the cells in a text file format by setting the choice parameter output_file_type to TEXT (the default for this operation; set to NONE for no text output), and the **string** parameter output_file_name (default "valsout.txt") to the desired text output file name. **DGGRID** will output the cell address and associated values for each cell, one cell per line, into the text file. The cell addresses are output in the form indicated by the **choice** parameter output_address_type (see **Appendix C**), using the character specified by parameter output_delimiter to separate any address components and to separate the address from the associated value.

By setting the choice parameter cell_output_control you can limit **DGGRID** to only output those cells which contain values (OUTPUT_OCCUPIED), or you can tell **DGGRID** to

output all cells (OUTPUT_ALL), in which case cells in which no values occurred will be output with a value of 0.0.

10. Presence/Absence Binning.

Setting the choice parameter dggrid_operation to BIN_POINT_PRESENCE tells **DGGRID** to perform presence/absence binning into the DGG(s) specified as per **Section 4**.

The input to this operation is a set of files (specified as described in **Section 7**), with each file containing a set of locations associated with one specific class of objects. If the input files are in TEXT format (**choice** parameter point_input_file_type has value TEXT), then each line in each input file should consist of a longitude and a latitude (both in decimal degrees), separated by the character indicated within double quotes in the **string** parameter input_delimiter. Each location can be followed, on the same line, by arbitrary text which is ignored by **DGGRID**; this arbitrary text must also be separated from the latitude/longitude address by the same input delimiter character.

DGGRID determines which classes occur in which cells in the specified DGG(s). The result for each cell is specified as a presence/absence vector, which is a string of 0's and 1's. The length of the string corresponds to the number of input files (and therefore to the number of classes). Each character in the string indicates whether the corresponding class is present (indicated by a 1) or not present (indicated by a 0) in that cell. The first character in the string corresponds to the class represented by the first file listed in input_files, the second character corresponds to the second file listed in input_files, and so forth.

If the **boolean** parameter output_presence_vector is set to TRUE (the default), for each output cell the calculated presence vector is output in a cell field with the field name specified in the **string** parameter output_presence_vector_field_name (default value "presVec").

If the **boolean** parameter output_count is set to TRUE (the default is FALSE), for each output cell the number of input points that are contained in that cell is output in the cell field with the field name specified in the **string** parameter output_count_field_name (default value "count").

If the **boolean** parameter output_num_classes is set to TRUE (the default is FALSE), for each output cell the number of classes that are contained in that cell (i.e., the number of 1's in the cell's presence vector) is output in the cell field with the field name specified in the **string** parameter output num classes name (default value "numClass").

In addition to the standard per-cell output described in **Section 5**, **DGGRID** can output the cells in a text file format by setting the choice parameter output_file_type to TEXT (the default for this operation; set to NONE for no text output), and the **string** parameter output_file_name (default "valsout.txt") to the desired text output file name. **DGGRID** will output the cell address and associated values for each cell, one cell per line, into the text file. The cell addresses are output in the form indicated by the choice parameter output address type (see **Appendix C**), using the character specified by parameter

output_delimiter to separate any address components and to separate the address from the associated value.

By setting the choice parameter cell_output_control you can limit **DGGRID** to only out-putting those cells which contain at least one class of object (OUTPUT_OCCUPIED) or have **DGGRID** output all cells (OUTPUT_ALL), in which case cells containing no input-specified locations would have presence/absence vectors consisting entirely of 0's.

page 22 of 59

11. Performing Address Conversions

Setting the **choice** parameter dggrid_operation to TRANSFORM_POINTS tells **DGGRID** to perform address conversion. The input file(s) are specified as described in **Section 7**, except that this operation currently supports only TEXT input.

Each line in each input file should consist of an address followed by optional arbitrary text. The components of the address (if any) must be delimited by the character indicated within double quotes in the **string** parameter input_delimiter, and if there is text following the address it must also be separated from the address by that character. The address must be a valid address under the address form indicated in the **choice** parameter input_address_type (see **Appendix C**). Address types other than GEO are interpreted as addresses in a DGG specified as per **Section 4**.

Each input address is transformed to an address of the form indicated by the **choice** parameter output_address_type (see **Appendix C**), and the resulting cells are output. The transformed cell address is output in a field named "name".

In addition to the standard per-cell output described in **Section 5**, **DGGRID** can output the cells in a text file format by setting the choice parameter output_file_type to TEXT (the default for this operation; set to NONE for no text output), and the **string** parameter output_file_name (default "valsout.txt") to the desired text output file name. **DGGRID** will output each transformed address, one cell per line, into the text file using the value of output_delimiter to separate any address components. If there was additional text on the input line following the address, then an output delimiter followed by that text is appended to the output line.

The TRANSFORM_POINTS operation can be used to determine the DGG cells that correspond to a set of input geodetic coordinates by using an input_address_type of GEO and an output_address_type corresponding to the desired DGG indexing (e.g., SEQNUM; see Appendix C). Note that this may result in the same cell being output more than once. Also note that DGGRID cannot be used to transform between two different DGGs in a single run, since only one DGG can be defined per run. However, this can be accomplished in two steps by first using DGGRID to transform cell addresses in the input DGG into GEO addresses, and then using a second run of DGGRID to transform those GEO addresses into the desired output DGG.

page 23 of 59

12. Outputting Grid Statistics

Specifying the value OUTPUT_STATS for the choice parameter dggrid_operation causes **DGGRID** to output a table of grid characteristics for the specified DGG (see **Section 4**). The output table will consist of all grid resolutions from 0 up to and including the specified DGG resolution. The values output for each resolution are the number of cells, the average area of a hexagonal cell in square kilometers, and the characteristic length scale (CLS). The CLS is the diameter of a spherical cap of the same area as a hexagonal cell of the specified resolution; this metric was suggested by Ralph Kahn. The calculation of average cell area uses the specified earth radius (see **Section 4.5**).

The **integer** parameter precision (default 7) specifies the number of digits to the right of the decimal point to output for each floating point value.

page 24 of 59

Appendix A. DGGRID Metafile Parameters

| Parameter Name (Type) | Description | Allowed Values (v) | Default | Notes | Used When |
|--|---|--|------------|--|---|
| bin_coverage (choice) | are values distributed over most of the globe or only a relatively small portion? | GLOBAL PARTIAL | GLOBAL | allows DGGRID to determine how to trade-off speed vs. memory usage | dggrid_operation is GENERATE_GRID_FROM_POINT, BIN_POINT_VALS OI BIN_POINT_PRESENCE |
| cell_output_control (choice) | designates which cells to output | OUTPUT_ALL OUTPUT_OCCUPIED | OUTPUT_ALL | OUTPUT_ALL - output all cells, even if no input values were associated with them OUTPUT_OCCUPIED - output only cells with associated input values | dggrid_operation is BIN_POINT_VALS OF BIN_POINT_PRESENCE |
| cell_output_file_name (string) | cell boundary output file name prefix | any | "cells" | | cell_output_type is AIGEN, SHAPEFILE, OT KML |
| cell_output_gdal_format (string) | cell boundary output file format | GDAL- compatible vector file format (see gdal.org) | GeoJSON | | cell_output_type iS GDAL |
| cell_output_type (choice) | cell boundary output file format | NONE AIGEN SHAPEFILE KML GEOJSON GDAL GDAL_COLLECTION | AIGEN | | |
| children_output_type (choice) | output cell spatial children? | NONE TEXT GDAL_COLLECTION | NONE | | |
| children_output_file_name (string) | spatial children output file name | any | "chd" | | children_output_type iS TEXT |
| clip_cell_res (integer) | resolution of clipping cells | 0 < v < r, where r is the currently specified DGG resolution | 1 | | dggrid_operation is GENERATE_GRID and clip_subset_type is COARSE_CELLS |

| Parameter Name (Type) | Description | Allowed Values (v) | Default | Notes | Used When |
|--|---|---|----------------|--|---|
| clip_cell_densification (integer) | number of points- per-edge densification for clipping cell boundaries | $0 \le v \le 500$ | 1 | v of ø indicates no densification | dggrid_operation is GENERATE_GRID and clip_subset_type is COARSE_CELLS |
| clip_cell_seqnums (string) | sequence number(s) of coarse clipping cells | seqNum1 seqNum2 seqNumN | | cell resolution given by clip_cell_res | dggrid_operation is GENERATE_GRID and clip_subset_type is COARSE_CELLS |
| clip_region_files (string) | space delimited list of files that specify grid clipping | any | "test.gen" | | dggrid_operation iS GENERATE_GRID |
| clip_subset_type (choice) | specifies how portion of DGG to generate will be determined | WHOLE_EARTH AIGEN SHAPEFILE GDAL SEQNUMS COARSE_CELLS | WHOLE_EARTH | | dggrid_operation is GENERATE_GRID; SEQNUMS is not supported if dggs_aperture_type is sequence; coarse_cells is only supported for hexagon grids |
| clip_type (choice) | method for determining whether a cell is included by a clipping polygon | POLY_INTERSECT | POLY_INTERSECT | | dggrid_operation iS GENERATE_GRID |
| clipper_scale_factor (integer) | number of cell inclusion tests to perform between outputting status updates | 1 ≤ <i>v</i> | 1000000 | | dggrid_operation iS GENERATE_GRID |
| clip_using_holes (boolean) | handle holes in input polygons? | TRUE FALSE | FALSE | | dggrid_operation iS GENERATE_GRID; clip_subset_type iS GDAL |
| collection_output_file_name (string) | collection output file name prefix | any | "cells" | see the last paragraph of Section 6 | |
| collection_output_gdal_format (string) | collection output file format | GDAL- compatible vector file format (see gdal.org) | GeoJS0N | see the last paragraph of Section 6 | |

| Parameter Name (Type) | Description | Allowed Values (v) | Default | Notes | Used When |
|--|--|---|---------------|--|--|
| densification (integer) | number of points- per-edge densification to use when generating cell boundaries | $0 \le v \le 500$ | 0 | v of ø indicates no densification | |
| dggrid_operation (choice) | specifies the operation to be performed by this run of DGGRID | GENERATE_GRID BIN_POINT_VALS BIN_POINT_PRESENCE TRANSFORM_POINTS OUTPUT_STATS | GENERATE_GRID | | always |
| dggs_aperture (integer) | desired DGGS aperture | 3, 4, 7 | 4 | | dggs_aperture_type is PURE |
| dggs_aperture_sequence (string) | the DGGS aperture sequence | string of 3's, 4's, and 7's in any order | "33333333333" | | dggs_aperture_type is SEQUENCE |
| dggs_aperture_type (choice) | is the aperture sequence pure or mixed? | PURE MIXED43 SEQUENCE | PURE | | dggs_topology is HEXAGON |
| dggs_num_aperture_4_res (integer) | number of aperture 4 resolutions in a mixed aperture sequence | $0 \le v \le 35$ | 0 | | dggs_aperture_type is MIXED43 |
| dggs_num_placements (integer) | number of grid placements to use | 1 ≤ <i>v</i> | 1 | if dggs_orient_ specify_type is not RANDOM all placements will be the same | |
| dggs_orient_output_ file_name (string) | name of file for output of multiple DGGS placement parameter values | any | "grid.meta" | | dggs_num_placements > 1 |
| dggs_orient_rand_seed (integer) | seed for orientation random number generator | $0 \le v$ | 77316727 | | dggs_orient_specify _type is RANDOM |

| update_frequency (integer) | number of cell inclusion tests to perform between outputting status updates | $0 \le v$ | 100000 | | dggrid_operation iS GENERATE_GRID |
| verbosity (integer) | amount of debugging output to display | $0 \le v \le 3$ | 0 | | |
| z3_invalid_digit (choice) | padding digit for unused resolutions in Z3 INT64 indexes | 0 1 2 3 | (will switch to 3 in version 9.0) | see Appendix C | |

Appendix B. Default Values for Preset DGG Types

A preset grid type can be specified using the choice parameter dggs_type. All preset grid types share the following default parameter values:

dggs_orient_specify_type: SPECIFIED

dggs_num_placements: 1
dggs_vert0_lon: 11.25

dggs_vert0_lat: 58.28252559

dggs vert0 azimuth: 0.0

dggs res specify type: SPECIFIED

The table below gives the values of other parameters that are set by each preset DGG type. Note that any preset parameter value can be overridden by explicitly specifying a different value for that parameter in the metafile anywhere after the dggs_type parameter value has been specified.

| dggs_type | dggs_ topology | dggs_ proj | dggs_ res_ spec | dggs_ aperture_ type | dggs_ aperture | dggs_num_ aperture_ 4_res | dggs_ aperture_ sequence |
|------------|-------------------|---------------|-----------------------|----------------------------|-------------------|---------------------------------|---|
| CUSTOM | HEXAGON | ISEA | 9 | PURE | 4 | N/A | N/A |
| SUPERFUND | HEXAGON | FULLER | 9 | MIXED43 | N/A | N/A | N/A |
| PLANETRISK | HEXAGON | ISEA | 11 | SEQUENCE | N/A | N/A | 433347777777777777777777777777777777777 |
| IGEO7 | HEXAGON | ISEA | 9 | PURE | 7 | N/A | N/A |
| ISEA3H | HEXAGON | ISEA | 9 | PURE | 3 | N/A | N/A |
| ISEA4H | HEXAGON | ISEA | 9 | PURE | 4 | N/A | N/A |
| ISEA7H | HEXAGON | ISEA | 9 | PURE | 7 | N/A | N/A |
| ISEA43H | HEXAGON | ISEA | 9 | MIXED43 | N/A | 0 | N/A |
| ISEA4T | TRIANGLE | ISEA | 9 | PURE | 4 | N/A | N/A |
| ISEA4D | DIAMOND | ISEA | 9 | PURE | 4 | N/A | N/A |
| FULLER3H | HEXAGON | FULLER | 9 | PURE | 3 | N/A | N/A |
| FULLER4H | HEXAGON | FULLER | 9 | PURE | 4 | N/A | N/A |
| FULLER7H | HEXAGON | FULLER | 9 | PURE | 7 | N/A | N/A |
| FULLER43H | HEXAGON | FULLER | 9 | MIXED43 | N/A | 0 | N/A |
| FULLER4T | TRIANGLE | FULLER | 9 | PURE | 4 | N/A | N/A |
| FULLER4D | DIAMOND | FULLER | 9 | PURE | 4 | N/A | N/A |

In addition to the listed parameters, the preset type SUPERFUND also sets the value of the parameter output_cell_label_type to SUPERFUND.

The preset type IGEO7 sets the additional parameters:

input_address_type:
HIERNDX

input_hier_ndx_system: Z7
input_hier_ndx_form: INT64

output_cell_label_type: OUTPUT_ADDRESS_TYPE

output_address_type: HIERNDX

output_hier_ndx_system: Z7
output_hier_ndx_form: INT64

Appendix C. DGG Address Forms

In **DGGRID** geographic coordinates are always expressed as:

longitude latitude

in decimal degrees. The parameters input_address_type and output_address_type refer to this address form as GEO.

DGGRID supports a number of address forms for specifying a particular cell in a DGG. These address forms are listed below according to their designation in the input_address_type and output address type parameters:

Q2DI - quad number and (i, j) coordinates on that quad

SEQNUM - linear address (1 to size-of-DGG)

 not supported for parameter input_address_type if dggs_aperture_type is SEQUENCE

PLANE - (x, y) coordinates on unfolded ISEA plane

 only supported for parameter output_address_type; not supported for parameter input_address_type

Q2DD - quad number and (x, y) coordinates on that quad

PROJTRI - triangle number and (x, y) coordinates within that triangle on the ISEA plane

VERTEX2DD - vertex number, triangle number, and (x, y) coordinates on ISEA plane

HIERNDX - address specified as described below

The following values are deprecated and will go away in version 9.0. The same address forms can be specified using HIERNDX:

```
ZORDER
ZORDER_STRING
Z3
Z3_STRING
Z7
Z7_STRING
```

If input_address_type or output_address_type has the value HIERNDX, then the specific address type is specified using input_hier_ndx_system/ output_hier_ndx_system and input_hier_ndx_form/output_hier_ndx_form respectively.

input_hier_ndx_system or output_hier_ndx_system specifies the hierarchical indexing system to use for input or output respectively. It takes the following values:

ZORDER - quad number and digit-interleaved Q2DI coordinates

- only available for hexagonal aperture 3 and 4 grids (not supported for aperture 7)
- Z3 base 3 Central Place Indexing (CPI) hierarchical index [Sahr 2019]
- only available for hexagonal aperture 3 grids
- 27 base 7 Central Place Indexing (CPI) hierarchical index [Sahr 2019]
- only available for hexagonal aperture 7 grids

input_hier_ndx_form or output_hier_ndx_form specifies the index representation for input or output respectively. It takes the following values:

INT64 - the index is packed into a hexadecimal 64 bit integer

• the digit used to fill unused resolutions in Z3 INT64 indexes is specified by the parameter z3_invalid_digit. The default value is 0 for **DGGRID** version 8.x, but will switch to 3 beginning with version 9.0.

DIGIT_STRING - consists of 2 characters representing the quad number followed by 1 character per hierarchical digit

page 37 of 59

Appendix D. Statistics for Some Preset ISEA DGGs

This appendix gives a table of characteristics for some hexagonal DGGs based on the ISEA projection that can be specified as preset DGG types using **DGGRID** (by setting metafile parameter dggs type as specified).

The internode spacing statistics given in these tables were calculated empirically on a symmetrical subset of the grid cells at each resolution. They will differ from the internode spacing values used by **DGGRID**, which are calculated on the plane (and are therefore only approximate).

All measurements assume a spherical earth with a radius of 6,371.007180918475 km (WGS84 authalic sphere radius).

For footnotes refer to the **Notes** section following all tables.

Notes

- * At every resolution 12 of the cells are pentagons and the remainder are hexagons.
- ** The 12 pentagons at each resolution have an area exactly 5/6 the area of a hexagon.

Appendix E. The EPA Superfund 500m DGGS

Denis White

US Environmental Protection Agency (retired) email: whitede@onid.orst.edu

Introduction

The **Superfund_500m** grid was commissioned by the US Environmental Protection agency for use in developing its Superfund Emergency Response Atlas. The grid is a hierarchically indexed icosahedral hexagonal discrete global grid (DGG) (Sahr et al. 2003) consisting of approximately 22 hectare hexagons, with approximately 500 meter distance between hexagon centers. This cell size is generated geometrically by creating a mixed aperture sequence of two aperture 4 subdivisions followed by 15 aperture 3 subdivisions.

It is not possible to create a network of equal area, equal shape, and equally spaced grid cells greater than twenty in number on the surface of a sphere. Thus one or more, often two or all three, of these characteristics are distorted to varying degrees across the surface. The approach used here starts with the twenty triangular faces of the icosahedron, creates a regular, equal area, equal shape, and equally spaced network of hexagons of the desired size on one or more of the planar triangles and then projects these cells to the surface of the globe. The distortion characteristics of this approach have been investigated by Kimerling et al. (1999) and Gregory et al. (2008).

Grid characteristics for the 10 addressable **Superfund 500m** resolutions are given in Table 1.

Grid Construction

The cells are generated as regular hexagons (and pentagons) on the surface of an icosahedron, oriented relative to the globe so as to be symmetrical about the equator. The cells are projected to longitude and latitude on a sphere with the authalic WGS84 radius (NAD 83 datum) using the inverse icosahedral projection of R. Buckminster Fuller (1975) as developed analytically by Robert Gray (1995) and John Crider (2008).

The **Superfund_500m** cell identifiers are an instance of Central Place Indexing (CPI). CPI (Sahr, 2011; Sahr, 2019) is a class of hierarchical indexing systems for pure and mixed aperture hexagonal DGGs, where the linear index assigned to each cell is constructed as a path address (Sahr 2008) on a multi-resolution discrete global grid system with the specified aperture sequence. A CPI addressing system was used in the initial design for a sampling system for the EPA's Environmental Monitoring and Assessment Program (White et al. 1992).

Table 1. Superfund 500m DGG Resolutions (see notes after table).

Table 1 Notes:

The **Superfund_500m** CPI system was designed to meet two design goals. First, the CPI approach allows the grid to have an intercell spacing of approximately 500 meters, which cannot be achieved with sufficient accuracy using a pure aperture grid system. Second, in order to take advantage of the pre-existing discrete global grid software tool **DGGRID** the cells needed to be hierarchically indexed in such a manner that the Christaller sets of each base cell are each restricted to a single **ij** coordinate system whose axes form two of the edges of a spherical quadrilateral formed by a pair of adjacent icosahedral faces.

These design goals were met by constructing a grid with base cells of valence 5 (i.e., with pentagonal voronoi areas) centered on each of the 12 vertices of an icosahedron and then applying the following aperture sequence:

To assign a unique hierarchical index to each cell, as well as to achieve the remaining grid design goals, the generator types *A-K* were defined with the following generator string representations:

A: A123456

B: **C**123**CCC**

C: *D*123*EED*

D: **F**123**IK**6

E: *J*123*GH*6

F: *D*123*EE*6

G: **DD**234**E**6

¹At every resolution 12 of the cells are pentagons and the remainder are hexagons.

²The 12 pentagons have an area exactly 5/6 the area of a hexagon.

³Measured in the plane of the Fuller projection space.

⁴Characteristic Length Scale (CLS): the diameter of a spherical cap of the same area as a cell of the specified resolution. This metric was suggested by Ralph Kahn.

H: EE2D456
 I: E1DD456
 J: E1D345E
 K: D123E5D

Two of the base cells on opposing sides of the icosahedron are assigned generator type A, while the remaining 10 base cells (centered on the remaining 10 icosahedral vertices) are assigned generator type B. Figures 1-3 illustrate the resolution 17 regions corresponding to the resolution 1 grid cells, numbered 10-51 (to avoid leading zeros in indexes). The resolution 0 base tiles centered on the resolution 1 cells labeled 10 and 51 are the two base cells that were assigned generator type A, which generates a single pentagonal cell at all resolutions.

Index Form

The base tiles of the **Superfund_500m** CPI indexes correspond to resolution 1 DGG cells, as illustrated in Figure 1. Base tiles 11-50 each have four hierarchical children at the aperture 4 resolution 2, which are assigned the additional digits 1-4. These resolution 2 cells each have three children at resolution 3, which are assigned the additional digits 1-3; this assignment continues recursively through the aperture 3 resolutions 3-17. The special base tiles 10 and 51 have a single hierarchical child at all resolutions, which is assigned the additional digit 1 at each resolution. In order to reduce the length of indexes, a first order compression is performed by grouping the aperture 3 resolution 3-16 digits into pairs and replacing each pair of digits with a digit value of 1-9.

The assignment of digits has been chosen so that all indexes form integers with the same number of digits, and so that possibly troublesome leading zeros can be avoided, even if redundant leading digits are removed from indexes when working in regions where this is possible.

Thus the full resolution 17 **Superfund_500m** CPI indexes are condensed into indexes with 11 digits, resulting in 10 addressable grid resolutions (see Table 1).

A **Superfund 500m** index at full resolution (resolution 9) has the 11-digit form:

BB49999993

where:

- BB is the 2-digit resolution 1 base tile cell with values 10-51,
- 4 is the resolution 2 aperture 4 digit with values 1-4,
- each *9* represent two successive combined aperture 3 digits for resolutions 3-16, with values 1-9 each, and
- the final 3 represents the extra aperture 3 at resolution 17, with values 1-3

Note that the resolution 9 footprint of base tiles 11-50 form approximate spherical diamonds on the surface of the globe, as illustrated in Figure 1. Figures 2 and 3 illustrate the resolution 9 indexing footprints of base tiles adjacent to base tiles 10 and 15 respectively. The hierarchical children at each aperture 3 resolution form a compact triangle; Figure 4 illustrates the pattern formed at resolution 9.

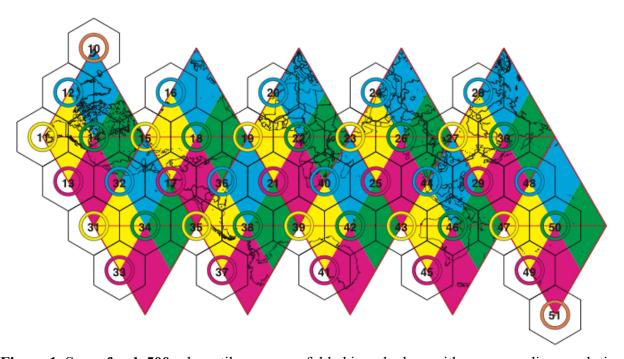

Figure 1. Superfund_500m base tiles on an unfolded icosahedron with corresponding resolution 9 indexing footprints. Cells within the footprint region of a base tile will have that base tile's index as the first two digits of the cell's index. Tiles 10 and 51 index only a single cell at all resolutions, centered on the corresponding base tile. Note that all tiles that are centered on a triangle vertex are actually pentagons on the sphere.

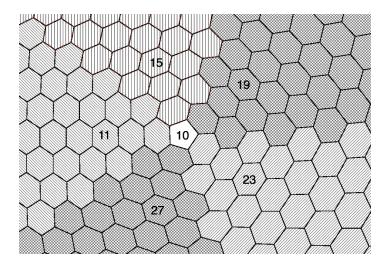

Figure 2. Region around base tile 10 at resolution 9.

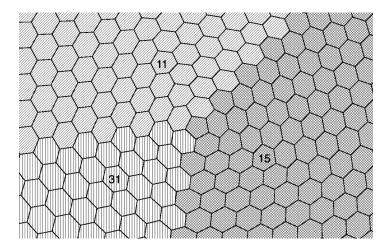

Figure 3. Region around base tile 15 at resolution 9.

Introduction

The efficiency of big data processing using modern massively distributed computing architectures is fundamentally limited by the efficiency of the algorithm used to shard the data – to partition that data for distributed storage and processing on multiple computing nodes. Efficiently sharding big data based on geospatial location has proven problematic. The most common geospatial location representations — vectors of floating point numbers representing latitude/longitude or planar map coordinates — do not naturally provide the global integer location index keys required for efficient sharding. The most common geospatial data structures, such as the quadtree and R-tree, have notoriously bad worst-case performance [Kanth et al. 1999; Arge et al. 2004], a serious concern when confronted with truly massive data sets. And because all of these systems are based on the pre-computer paper-based mapping paradigm of rectangular planar regions representing portions of the topologically spherical globe, attempting to use any of these representations on truly global big data sets exposes their intrinsic geometric weaknesses, which include areas of extreme distortion, singularities, and data under/over-sampling.

Efficient real-time analysis of multi-source global geospatial big data requires a common, consistent, multi-resolution geospatial reference frame, which naturally partitions the spherical earth into regular, integer-indexable, shards. In this paper we will systematically evaluate the available design options in order to develop the most advanced such system possible.

System Design

In order to address the issues with traditional approaches to location representation in next generation geospatial systems, researchers have recently focused on location representations based on the multi-resolution recursive partition of spherical polyhedra, called Discrete Global Grid Systems (DGGS) [Goodchild 2010; Goodchild et al. 2012]. Designing a specific DGGS requires making a series of basic design choices [Sahr et al. 2003]. Because DGGS's are the most advanced geospatial discretization approach available to us, we choose to use a DGGS approach to designing the system.

In designing a DGGS, a base polyhedron must first be chosen on which the grid will be constructed. This choice establishes the underlying symmetries of the system. We choose the icosahedron as our base polyhedron, because it has the smallest face size amongst the platonic solids and hence the smallest distortion amongst equivalent face-centered polyhedral projections.

Second, we must choose a method for partitioning the surface of the icosahedron. Researchers in numerous fields (see the survey in [Sahr, 2011]) have consistently concluded that hexagons are the optimal choice for discrete gridding and location representation. The superiority of hexagons for all forms of discrete location representation stems from their unique geometric properties: amongst the three regular polygons that tile the plane (triangles, squares, and hexagons), hexagons are the most compact, they quantize the plane with the smallest average error [Conway and Sloane 1998], and they provide the greatest angular resolution [Golay 1969]. Unlike square and triangle grids, hexagon grids display uniform adjacency; each cell in a grid of hexagons has six neighbors, all of which share an edge with it, and all of which have centers exactly the same distance away from its center. We therefore choose to use a grid of hexagons. Note that the sphere cannot be fully tiled with hexagons; any hexagonal tiling using an icosahedral basis will always have 12 pentagonal grid cells, one centered at each of the icosahedron's vertices.

The third basic DGGS design choice specifies the orientation of the icosahedron relative to the earth's surface. We choose the standard Terra Cognita orientation, which is symmetrical about the equator and places only one icosahedral vertex/pentagonal cell on land, the minimum number known for a symmetrical orientation (see Figure 1).

Figure 1. A spherical icosahedron with standard Terra Cognita orientation.

Next we choose a method for transforming between the surface of the earth and the surface of the icosahedron upon which the grid of hexagons is constructed. Equal area cells greatly simplify statistical data analysis, and therefore we choose as our transformation the only known equal area icosahedral DGGS projection: the Icosahedral Snyder Equal Area (ISEA) projection [Snyder, 1992]. We further specify that cell center points will be calculated in the ISEA projection space.

The final design choice we must make is to chose a recursive method for constructing multiple resolutions of hexagon grids, ideally one in which the grids at different resolutions have a regular hierarchical relationship that can be exploited during analysis. Such grids are often constructed by specifying a sequence of apertures, or ratios between cell areas at a given grid resolution and the next coarser resolution, with research primarily focusing on the three "central place" apertures 3, 4, and 7 [Sahr 2003] (see Figure 2).

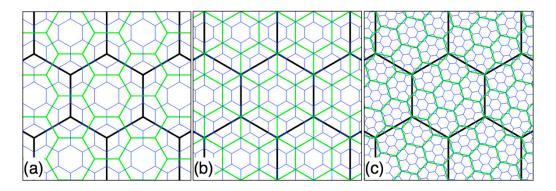

Figure 2. Three resolutions of three multi-resolution hexagon grid apertures: (a) aperture 3, (b) aperture 4, and (c) aperture 7.

In the case of an icosahedral/hexagonal DGGS the sequence begins with 12 fixed-size pentagons (forming a spherical dodecahedron), usually designated as resolution 0. A chosen sequence of apertures then determines the cell area and intercell-spacing at each coarser grid resolution. It would be desirable to have one grid resolution with cells as close as possible to 1 km² in area, since that is both a generally familiar size as well as a reasonable base granularity for analysis. We evaluated all possible combinations of apertures 3, 4, and 7, and found that a sequence of eleven resolutions containing three aperture 3's, two aperture 4's, and six aperture 7's creates a grid of hexagons with an area of 1.002464 km², the closest it is possible to achieve to 1 km² in area with this approach.

Any sequence consisting of the required mix of apertures will achieve our 1 km² cell area, but we want to arrange their ordering for optimal value. We chose to do an initial aperture 4 in order to center cells on the north and south pole, which lie on the mid-points of icosahedron edges in the Terra Cognita orientation (see Figure 3).

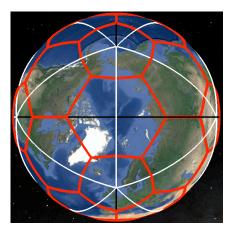

Figure 3. Cell boundaries for the first grid resolution overlaid on base icosahedron. Note the cell centered on the North Pole.

We choose to order the remaining apertures from smallest to largest, minimizing the number of cells in the coarser resolution of the DGGS to enable efficient coarse filtering operations. We also specify that additional grid resolutions, beyond our 1 km² resolution 11, should have an aperture of 7. Ordering the apertures as we do also has the effect of making the system geometrically a pure aperture 7 system at the finest resolutions; it should be noted that, of the three central place apertures, aperture 7 is geometrically the most efficient choice for sharding, since it forms unambiguous, balanced hierarchies that are optimally compact and "hexagon like" across resolutions.

We have now completed the design choices needed to specify our DGGS. Table 1 gives some characteristics of the first 12 resolutions of the system, and Figure 4 illustrates the cell boundaries of one grid resolution.

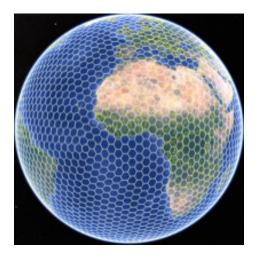

Figure 4. Grid cell boundaries for resolution 5 of the PlanetRisk DGGS.

| res | anartura | #cells | hex area (km²) | inter-node spacing (km) | | | | |

Conclusions

In this paper we have developed a discrete location reference system for global geospatial big data analysis, optimized for efficient location-based sharding. We evaluated the most advanced design options available to us, making optimal choices at each step, to develop what we believe to be the most advanced such system currently known: the PlanetRisk Discrete Global Grid System (DGGS).
